**Appendix S1: Supplementary data****Table S1.** Estimates of local species composition at 39 sites in Middle America based on data summarized by Duellman (2001). Locality numbers correspond to Table 2. References for body size and larval habitat data are found in Table S2.

Locality and elevation (country, state, specific location)	Species present	Body size	Larval habitat	Hylid clade	Subclade within Middle American clade
1) Mexico, Sonora, Alamos; 597 m	<i>Pachymedusa dacnicolor</i>	82.6	pond	Phyllomedusinae	
	<i>Smilisca baudinii</i>	76.0	pond	Middle American	<i>Smilisca</i> clade
	<i>Smilisca fodiens</i>	62.6	pond	Middle American	<i>Smilisca</i> clade
2) Mexico, Sinaloa, Mazatlan; 9 m	<i>Pachymedusa dacnicolor</i>	82.6	pond	Phyllomedusinae	
	<i>Smilisca baudinii</i>	76.0	pond	Middle American	<i>Smilisca</i> clade
	<i>Smilisca fodiens</i>	62.6	pond	Middle American	<i>Smilisca</i> clade
	<i>Tlalocohyla smithii</i>	26.0	pond	Middle American	<i>Tlalocohyla</i>
	<i>Diaglena spatulata</i>	85.9	pond	Middle American	<i>Smilisca</i> clade
3) Mexico, Durango, El Salto; 2603 m	<i>Hyla eximia</i>	35.0	pond	Middle American	<i>Hyla</i>
4) Mexico, Jalisco, Chamela; 11 m	<i>Dendropsophus sartori</i>	26.0	pond	<i>Dendropsophus</i>	
	<i>Exerodonta smaragdina</i>	26.0	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Pachymedusa dacnicolor</i>	82.6	pond	Phyllomedusinae	
	<i>Smilisca baudinii</i>	76.0	pond	Middle American	<i>Smilisca</i> clade
	<i>Smilisca fodiens</i>	62.6	pond	Middle American	<i>Smilisca</i> clade
	<i>Tlalocohyla smithii</i>	26.0	pond	Middle American	<i>Tlalocohyla</i>
	<i>Diaglena spatulata</i>	85.9	pond	Middle American	<i>Smilisca</i> clade
<i>Trachycephalus venulosus</i>	101.0	pond	Lophiohylini		

Moen et al.

2

5) Mexico, Michoacan, Nueva Italia (between Rio Marquez and Cuatro Caminos); 412 m	<i>Pachymedusa dacnicolor</i>	82.6	pond	Phyllomedusinae	
	<i>Smilisca baudinii</i>	76.0	pond	Middle American	<i>Smilisca</i> clade
	<i>Smilisca fodiens</i>	62.6	pond	Middle American	<i>Smilisca</i> clade
	<i>Tlalocohyla smithii</i>	26.0	pond	Middle American	<i>Tlalocohyla</i>
	<i>Diaglena spatulata</i>	85.9	pond	Middle American	<i>Smilisca</i> clade
6) Mexico, D.F., Xochimilco; 2240 m	<i>Hyla eximia</i>	35.0	pond	Middle American	<i>Hyla</i>
7) Mexico, Guerrero, Puerto del Gallo; 2078 m	<i>Charadrahyla trux</i>	81.0	stream	Middle American	<i>Charadrahyla</i> clade
	<i>Exerodonta melanomma</i>	29.9	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Exerodonta pinorum</i>	34.5	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Plectrohyla hazelae</i>	38.6	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Plectrohyla mykter</i>	42.3	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Plectrohyla pentheter</i>	52.1	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Plectrohyla thorectes</i>	34.2	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Ptychohyla leonardschultzei</i>	35.6	stream	Middle American	<i>Ptychohyla</i> clade
8) Mexico, Oaxaca, Puerto Escondido; 2 m	<i>Dendropsophus sartori</i>	26.0	pond	<i>Dendropsophus</i>	
	<i>Pachymedusa dacnicolor</i>	82.6	pond	Phyllomedusinae	
	<i>Scinax staufferi</i>	29.0	pond	<i>Scinax</i>	
	<i>Tlalocohyla smithii</i>	26.0	pond	Middle American	<i>Tlalocohyla</i>
	<i>Trachycephalus venulosus</i>	101.0	pond	Lophiohylini	
	<i>Diaglena spatulata</i>	85.9	pond	Middle American	<i>Smilisca</i> clade
9) Mexico, Oaxaca, San Gabriel Mixtepec; 1768 m	<i>Charadrahyla altipotens</i>	75.0	stream	Middle American	<i>Charadrahyla</i> clade
	<i>Exerodonta juanita</i>	35.8	stream	Middle American	<i>Plectrohyla</i> clade
	<i>Exerodonta melanomma</i>	29.9	stream	Middle American	<i>Plectrohyla</i> clade

**Table S3.** Morphometric data for hyloid frogs. All measurements are in millimeters and were conducted on males.

Variables are described in the text and labeled here as follows: (1) snout-to-vent length (SVL); (2) tibia length (TIBL); (3) foot length (FOOT); (4) head length (HLEN); (5) head width (HWID); (6) interorbital distance (IOD); (7) internarial distance (IND); (8) eye-to-nostril distance (ENOS); (9) eye diameter (EYE); (10) hand length (HNDL); (11) thumb length (THBL); (12) radioulnar length (RDL); (13) maximum width of terminal digit of finger 3 (DIG3); and (14) tympanum width (TYMP).

For Review Only

**Table S4.** Results of principal components analysis (PCA) on the hylid morphometric data (Table S3), showing the loadings of each original variable on PC1 (left) and the proportion of the total variation represented by each PC axis (right). Variable acronyms are as above in Table S3. We only present the principal components loadings for the first PC axis due to the low amount of variation represented by all other axes. “All hylids” represents a PCA conducted on the data from a sample of all hylid species (i.e., regardless of region), while “MA hylids” represents the same analysis conducted on a subset of the data that includes only Middle American species.

Variable	<i>PC1 loadings</i>		PC Axis	<i>% Variation</i>

## 1 **Figure legends**

2  
3  
4  
5  
6  
7  
8 **Figures S1–S3.** Phylogeny of Hylidae that was used for all analyses, estimated by (1)  
9  
10 separate Bayesian analyses of each major South American clade (from Moen and  
11  
12 Wiens 2009) and the Middle American Clade (Smith et al. 2007), (2) converting branch  
13  
14 lengths into units of time using the program r8s, and (3) connecting these clades  
15  
16 together by placing on an ultrametric phylogeny (with branch lengths in units of time) of  
17  
18 the Hylidae, as estimated by Wiens et al. (2006b). See Methods for further details.  
19  
20 Branch lengths are in units of time, with the scale bar reflecting divergence times  
21  
22 estimated using the younger set of calibration dates. Branch colors reflect  
23  
24 biogeographic designations (for species at tips) and ancestral-state estimates (for  
25  
26 internal nodes), estimated under the DEC model of Ree and Smith (2008). This model  
27  
28 distinguishes between range evolution along branches with changes that occur at  
29  
30 cladogenesis events; thus, we show changes as occurring mid-branch (for changes  
31  
32 along branches) or as vertical branches differing from their common ancestor (for  
33  
34 changes at cladogenesis). Note that the position of changes along branches could not  
35  
36 be inferred, so our mid-branch designation for changes is arbitrary and was chosen for  
37  
38 visual clarity. Branch colors reflect states with the highest likelihood, and dashed  
39  
40 branches represent cases where alternative reconstructions fell within two ln-likelihood  
41  
42 units (Ree and Smith 2008). In most of these latter cases the displayed resolution still  
43  
44 had a much higher likelihood than all other possible resolutions, with the exception of  
45  
46 the nodes in the vicinity of the Middle American *Hyla* in Fig. S3. Because of the  
47  
48 extreme amount of ambiguity in this case (no potential resolution had a normalized  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

Moen et al.

1  
2  
3 24 likelihood higher than 0.44 and 3–5 alternative resolutions were possible), we  
4  
5 25 considered it most likely that *Hyla* recolonized Middle America only once. However,  
6  
7  
8 26 considering this clade as representing multiple colonization events did not influence our  
9  
10 27 results (not shown).  
11  
12  
13 28

14  
15 29 **Figure S4.** Effect of community size on the power of ROTI null model analyses. The  
16  
17 30 vertical axis is represented as  $1 - P$ , or one minus the  $P$ -value from the likelihood ratio  
18  
19 31 test (i.e., values  $\geq 0.95$  favor rejecting the null model). Thus, these are analogous to  
20  
21 32 power curves, but are different in that power curves instead compare the proportion of  
22  
23 33 overlap of an alternative distribution with that of a null distribution. Note that we varied  
24  
25 34 the ROTI continuously from 0.0 to 1.0 to aid visual demonstration of the change in  
26  
27 35 power, but this also means that many of these ROTIs correspond to fractions of ISE  
28  
29 36 events per community (especially in smaller communities), so it should be understood  
30  
31 37 that many of the values along these curves are only of theoretical interest.

## Appendix S2: Null models

In this section, we develop null models for testing whether the value of a given index for a given community differs significantly from expectations based on chance. We focus on the ROTI (Regional Origin Trait Index), which is the major emphasis of our paper. For the CTDI (Community Trait Dispersal Index), development of a null model is very difficult because one cannot simply shuffle species among communities (the basis for most null models in community ecology). Shuffling species among communities would change the number of communities in which each trait origin is represented, a value upon which this index is calculated. Determining null values for the CTDI seems impossible without an extensive simulation study with a very large parameter space.

Below we create a null model for the ROTI using the hypergeometric distribution, which relates the fraction of species with character-state origins due to ISE vs. ECD (i.e., the ROTI) in a given community with that expected based on a random sampling of species from a regional species pool. We then discuss and illustrate how changes in the regional species pool and number of species in communities influence the ROTI, and we present results from these null models for Middle American hylid communities. Finally, we conclude with a brief discussion on the realism of these null models and how these considerations affect the interpretation of one's results.

### *The Basic Model*

1  
2  
3 We examine the significance of a given value of ROTI for a community,  
4 given the overall frequency of ISE and ECD events among species within the  
5 region as a whole. Thus, we ask how deviant a given community's ROTI is when  
6 considered in light of the overall number of species whose character states were  
7 the consequence of ISE and ECD events within the region as a whole. As a  
8 simple example, we might see a high ROTI in communities composed of species  
9 derived from a within-region radiation in which many character states originated  
10 in the region by in-situ evolution. Conversely, communities composed of many  
11 recent colonists from outside the region may have a significantly low ROTI.

19  
20  
21  
22  
23

24 Values for a null model can be generated in at least three different ways.  
25  
26 First, one could conduct a simulation, in which one simulates the details of a  
27 system but without the process of interest. Second, one could reshuffle the data  
28 in a way that creates a null distribution that does not reflect the process of  
29 interest (e.g., shuffle species among communities to assume ecological  
30 equivalence). Third, if a reasonable probability distribution can be specified for  
31 the process of interest, one can model the process and calculate probabilities  
32 directly. We take this third approach here.  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42

43 We test for the statistical significance of the ROTI by considering  
44 community assembly as a process of sampling species without replacement from  
45 a larger regional pool, using the hypergeometric probability distribution (Sokal  
46 and Rohlf 1995). Using this distribution, one can calculate the probability of  
47 observing the number of species with a character state derived from ISE as a  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

consequence of random assembly versus assembly in which one type of regional origin (ISE or ECD) might be favored.

The hypergeometric probability distribution is a model of sampling from a population without replacement, where the “population” here is the regional pool of all Middle American hyliid species (see below for variations), and the “sample” is a community. This distribution is appropriate when sampling units can be classified into discrete categories; in this case, a sampled species has a character state (body-size class or larval habitat type) that can be classified as having originated in the region by an ISE or ECD event. We can model the statistical significance of the ROTI in this way because it is calculated as the number of species with a character-state that originated through ISE in the region ( $d_I$ ) divided by the total number of species in the community ( $n$ ). Thus, under the null model of random assembly, the probability that, for a given character, a community of size  $n$  has  $d_I$  species with ISE is

$$P(x = d_I | n, D_I, D_E) = \frac{\binom{D_I}{d_I} \binom{D_E}{n - d_I}}{\binom{D_I + D_E}{n}} \quad (1)$$

where  $D_I$  and  $D_E$  are the total number of species with character-state origins by ISE and ECD, respectively, within the sampled population (i.e., the regional source pool; Sokal and Rohlf 1995). Note that the term “ $n - d_I$ ” could also be

represented by  $d_E$ , the number of species whose character state originated by ECD.

The hypergeometric distribution as described above is appropriate for obtaining the probability under “random” assembly of a given number of species in a community with their character states from ISE. However, various processes may lead to a predominance of species that trace their traits to ISE or ECD (e.g., a community that is more isolated from dispersal from other regions, due to geographic or ecological barriers, may have less species with traits derived through ECD). In other words, if more species with character states that originated in a region through ISE (or ECD) enter the community during community assembly, then a bias in “sampling” from the regional pool would exist. To incorporate this bias, we use the non-central hypergeometric distribution (McCullagh and Nelder 1989). This distribution incorporates additional parameters to estimate the bias in sampling from the different categories. Here, the sampling biases for ISE and ECD are represented as  $\omega_I$  and  $\omega_E$ , respectively. Thus, the probability of a particular number of species within a community whose character-state origin was by ISE, conditioned on the sampling biases, regional pool ( $D_I$  and  $D_E$ ), and number of species within the community ( $n$ ) is

$$P(x = d_I | \omega_I, \omega_E, n, D_I, D_E) = \omega_I^{d_I} \omega_E^{n-d_I} \frac{\binom{D_I}{d_I} \binom{D_E}{n-d_I}}{\binom{D_I + D_E}{n}} Q^{-1} \quad (2)$$

where  $Q$  is a normalization constant. Because  $\omega_I$  and  $\omega_E$  are interdependent (e.g., as one goes up the other must go down), we reparameterized the equation (following Munch and Conover 2003; see also McCullagh and Nelder 1989) to compare the bias parameters to each other, with the ratio  $\psi = \omega_I / \omega_E$ . Additionally, the terms that do not depend on  $d_I$  and  $d_E$ , can be taken out of the equation because those constant terms will also be in the normalization constant and thus will cancel out.

$$P(x = d_I | \psi, n, D_I, D_E) = \left( \frac{\psi^{d_I}}{d_I!(n-d_I)!(D_I-d_I)!(D_E-n+d_I)!} \right) Q^{-1} \quad (3)$$

where the normalization constant,  $Q$ , is equal to

$$Q = \sum_{i=0}^n \left( \frac{\psi^i}{i!(n-i)!(D_I-i)!(D_E-n+i)!} \right) \quad (4)$$

The standard (random assembly) and non-central hypergeometric models are compared via a likelihood ratio ( $LR$ ) test, which can be used to compare nested models (Edwards 1972). Here, the random assembly model is a special case of (i.e., nested within) the biased assembly model when  $\psi = 1$ . The  $LR$ -test statistic is

$$LR = 2 \ln \frac{\ell(\psi = \hat{\psi})}{\ell(\psi = 1)}$$

(5)

where  $\hat{\psi}$  = maximum likelihood estimate of the bias parameter. Given the random assembly model, this  $LR$  is expected to be asymptotically distributed as  $\chi^2_{p,\alpha}$ , where  $p$  = the number of free parameters differing between the two models and  $\alpha$  = the desired level of statistical significance. In this case,  $p = 1$  and we set  $\alpha = 0.05$ . We calculated the bias parameter estimate and likelihoods of the two models in MatLab (ver. 6.5, The MathWorks Inc., Natick, MA), and the code is available from the authors upon request.

We note here two important considerations. First, in theory, one could instead simply conduct an exact randomization test (sensu Sokal and Rohlf 1995, p. 803). Here, one calculates the probability of obtaining the observed and more deviant outcomes under the null model, in this case the standard hypergeometric model [i.e., random assembly; equation (1) above], and compares this probability to a significance value, such as  $\alpha = 0.05$ . In the current framework, one would be asking how probable it is to obtain the observed or more extreme (i.e., closer to 0.0 or 1.0) ROTIs given the null model.

Under most circumstances, this should give very similar results to our approach. However, the advantage of our approach is that it is more general, allowing investigators to extend tests to more complicated questions. For example, the approach outlined above will be necessary if one wants to calculate whether two communities differ from each other (i.e., compare the likelihood of each community having its own unique bias parameter versus the likelihood that their

1  
2  
3 bias parameters are the same). Second, the number of species within a  
4  
5 community (community size) is the effective sample size in these analyses, so  
6  
7 this number will influence the power of statistical analyses. To quantitatively  
8  
9 examine the influence of community size, we also conduct a simple simulation,  
10  
11 varying the number of species in artificial communities and testing whether the  
12  
13 ROTI was significantly different than the random expectation. To do this, we  
14  
15 tested similar ROTI values (varied continuously from 0.0 to 1.0) for increasingly  
16  
17 larger communities (varied from 2 to 30 species). For these analyses we used a  
18  
19 regional pool of 180 species, 90 each with character-state origins due to ISE and  
20  
21 ECD ( $D_I = 90$ ,  $D_E = 90$ ).

### 29 *Variations on the Model*

30  
31 In theory, statistical significance of the ROTI may be influenced by the size  
32  
33 or characterization of the regional species pool. Varying the regional pool, then,  
34  
35 may reveal important drivers of significantly high or low ROTI values. For  
36  
37 example, altering the probabilities of randomly sampling species from the  
38  
39 regional pool in proportion to dispersal ability may reveal whether dispersal ability  
40  
41 is more strongly correlated with one type of character-state origin (e.g. ECD) than  
42  
43 another (ISE; see below). Alternatively, changing the geographic size of the  
44  
45 regional pool may suggest at what scale dispersal limitation breaks down. For  
46  
47 example, given a significantly high ROTI, we might suspect that localized ISE  
48  
49 events and dispersal limitation lead to a predominance of ISE in a community  
50  
51  
52

54  
55  
56  
57  
58  
59  
60

1  
2  
3 (and thus a high ROTI). In this case, reducing the geographic extent of the  
4 regional pool should result in a ROTI going from significant to non-significant.  
5  
6

7  
8 To address these situations, we examine two variations on the regional  
9 species pool. We first alter the regional pool by weighting species by a proxy for  
10 dispersal ability (see below for details). Second, we vary the geographic extent  
11 of the regional pool for communities in Costa Rica and Panama.  
12  
13  
14  
15

16  
17 One way to alter the regional pool would be to weight species  
18 representation in the regional pool by overall abundance in the region, by the  
19 size of their geographic range within the region relative to the region's size as a  
20 whole, by known dispersal ability (which is unknown for many organisms), or by  
21 their frequency in the communities of the region. Herein we examine the latter  
22 weighting scheme [corresponding to the "occurrence distribution" of Connor and  
23 Simberloff (1978)]. In this analysis, our overall regional pool was limited to the  
24 species that occurred in the communities we considered, and each species  
25 occurred in the regional pool as many times as it occurred across our entire  
26 sample of communities (e.g., a species that occurred in five communities was  
27 listed five times in the regional pool, whereas a species that was only in one  
28 community was listed once, as before). The consequence of this  
29 characterization of the regional pool is to upweight the species that have  
30 dispersed widely throughout the region and downweight those with limited  
31 distributions. This might be more reasonable in cases where one type of trait  
32 origin (ISE or ECD) is found in widespread species, thus reducing the  
33 significance of seeing many communities with high amounts of that type of trait  
34

2  
3 origin. For Middle American hylids, the original regional pool contains 73 species  
4 with character-state origins due to ISE of body size and 82 due to ECD for body  
5 size (i.e., a ratio of 73:82), and a ratio of 119:37 for larval habitat, whereas the  
6 ratios under the frequency-weighted regional pools were 146:110 and 151:105,  
7 respectively.  
8  
9

10  
11  
12  
13  
14  
15 A second way to alter the regional pool is to change the geographic scale  
16 over which it occurs. Certainly, an optimal regional pool would be one within  
17 which all species can be expected to disperse freely (an assumption of many  
18 sampling models of community assembly, but see below for a discussion on this  
19 assumption in our model), but it can be quite difficult in practice to specify exactly  
20 such a pool (Connor and Simberloff 1978, Graves and Gotelli 1993). Thus, we  
21 examined the effect of progressively larger regional pools. For this analysis we  
22 examined the communities of Costa Rica and Panama, testing significance with  
23 the “regional pool” set at the scale of the individual countries, the two countries  
24 combined, and all of Middle America (cf. Swenson et al. 2006). The ratios of ISE  
25 to ECD in the two countries combined were 20:31 and 27:25 for body size and  
26 larval habitat, respectively. The ratios for Costa Rica only were 18:22 and 24:17,  
27 and those for Panama were 16:29 and 22:23 for body size and larval habitat,  
28 respectively.

## 50 *Results*

51  
52  
53 The results for our null model analyses of each community’s ROTI are  
54 presented in Tables S5–S6. In general, we found only communities with the  
55  
56  
57  
58  
59  
60

1  
2  
3 most extreme deviations from the regional pool (i.e., very high or low ROTI) to be  
4 statistically significant. Though many communities were close to the null  
5 expectation of the regional pool (and thus would not be expected to be significant),  
6 our data also illustrate the low statistical power experienced by analyses of small  
7 community size (e.g., community 1 vs. 2 for body size ROTI; Table S5).  
8  
9

10  
11 Our simulation results of varied community size are presented in Fig. S4,  
12 showing the large increase in power with moving from communities of  $n = 2$  (no  
13 ROTIs significant) to those of  $n = 10$  (ROTI = 0.0–0.20 significantly low, 0.80–1.0  
14 significantly high) to  $n = 20$  (ROTI = 0.0–0.29, 0.71–1.0 significant). However, it  
15 should be noted that the primary aim of our empirical study of treefrogs is not to  
16 test for significant deviations from random expectations, but rather to test for  
17 correlates of ROTI among communities (e.g., with elevation).  
18  
19

20  
21 Modification of the regional species pool strongly influenced the results.  
22  
23  $P$ -values for the ROTIs of both body size and larval habitat were often quite  
24 different when comparing the “standard” regional pool with the regional pool  
25 constructed by weighting species by their frequency across communities, though  
26 they were still correlated (Body size:  $r_s = 0.624$ ,  $P < 0.0001$ ; Larval habitat:  $r_s =$   
27  $0.619$ ,  $P < 0.0001$ ). For body size, all ROTI values statistically significant under  
28 one regional pool were also significant under the other (Table S5). However, for  
29 larval habitat, statistical significance often changed based on the regional pool  
30 (Table S6), possibly reflecting the larger asymmetry in the ISE:ECD ratio in these  
31 two pools for larval habitat relative to the regional pools for body size.

When we varied the geographic scale of the regional pool for Panamanian communities, the general consequence of reducing the size of the regional pool was to make results more liberal for body size and more conservative for larval habitat. These results seem to be influenced largely by the relative shift in the symmetry of ISE to ECD events represented in the regional pool. Despite this tendency, communities with a significant larval habitat ROTI under the Middle American regional pool (i.e., the largest pool) were still statistically significant when the regional pool was reduced to Panama alone (i.e., the smallest pool). Similar relationships extended to the analyses of Costa Rican communities. In both cases, it is clear from the results that the consequences of altering the regional pool will be highly data dependent, contingent on the ratio of ISE to ECD events in the regional pool. Thus, we suggest that future analyses under this framework similarly examine the influence of the regional pool and base conclusions under the most realistic regional pool if the results are not robust to the regional pool specification.

#### *Discussion of Model Assumptions*

We note here two important model considerations. First, the idea of sampling from a regional pool to assemble communities is not realistic in many cases. In particular, here we are inferring the importance of evolution within a region (ISE) versus character-state origins from dispersal from outside the region (ECD). Clearly, then, the idea of a static regional pool from which species assemble into communities is not realistic. For ISE, character-states are

1  
2  
3 presumably generated by in-situ evolution within certain types of communities  
4  
5 (which are then represented by a sample of that type of community in our  
6  
7 analyses, such as stream breeders in montane forests in hylids). In other words,  
8  
9 at some level, the communities are helping to generate the regional pool, rather  
10  
11 than strictly vice versa. Despite this discrepancy between the null model and our  
12  
13 understanding of the evolution of a regional pool of species, we see our null  
14  
15 models as useful because they form a method to point out whether a ROTI is  
16  
17 significantly higher or lower under one type of random expectation. Violations of  
18  
19 the null model form a basis for further investigation into the processes that create  
20  
21 the patterns we are testing (instead of a basis for rejecting the methodology).  
22  
23  
24  
25  
26

27         Second, many models of random community assembly from a regional  
28  
29 pool assume no dispersal limitation among sites (i.e., all species within the  
30  
31 regional pool could, in principle, be found in a given community; Vamosi et al.  
32  
33 2009). However, this is not an assumption of the ROTI. In fact, without dispersal  
34  
35 limitation, we might not expect to see any significant deviations from a random  
36  
37 draw from the species pool. For example, evolution within a small area within a  
38  
39 region (ISE), coupled with dispersal limitation (e.g., at high elevations), would  
40  
41 suggest that most species within communities from that area will have their  
42  
43 character-state origins from ISE and thus would have a high ROTI.  
44  
45  
46  
47

48         It is important to distinguish here between our null model for the ROTI and  
49  
50 the increasing use of very similar null models for detecting competition,  
51  
52 environmental filtering, or other phenotype-specific processes in community  
53  
54 assembly (e.g. Webb 2000; Kraft et al. 2007). In order to isolate the role of  
55  
56  
57  
58  
59  
60

1  
2  
3 specific processes in community assembly (such as competition), one must  
4  
5 assume dispersal equivalency in both the null and alternative models. However,  
6  
7 the ROTI only relates to how many species within a community have a character  
8  
9 state that originated within the region via ISE or ECD and makes no reference to  
10  
11 the value of the character state itself (which *is* important in the former case of  
12  
13 determining such processes as environmental filtering and competition). Thus,  
14  
15 dispersal limitation is a perfectly valid alternative model to explain why a  
16  
17  
18  
19  
20 community has a high ROTI, as in the example given above.

For Review Only

**Table S5.** Results of ROTI null model analyses for body size, showing ROTI value for each community and its associated *P*-value under different regional pools. Community numbers refer to communities as listed in Table S1.

Communities with significant *P*-values are boldfaced.

Community	Number of species	Body Size ROTI	Whole region	Freq. weighted	Costa Rica + Panama	Costa Rica	Panama
